Rutherford scattering data

The following data is from Geiger and Marsden's 1913 paper where y is the number of scattering events.

The differential cross section for Rutherford scattering is

$$d\sigma \propto \frac{d\Omega}{4\sin^4(\theta/2)} = \frac{d\Omega}{(1-\cos\theta)^2}$$

For the Geiger and Marsden data $d\Omega$ is a constant hence

$$d\sigma \propto \frac{\Delta\Omega}{(1-\cos\theta)^2}$$

Let f(k) be the probability mass function

$$f(k) = \Pr(\theta = \theta_k) = C d\sigma \Big|_{\theta = \theta_k}$$

where C is a normalization constant. Let C absorb the constants in $d\sigma$ and write

$$f(k) = \frac{C}{(1 - \cos \theta_k)^2}$$

To find C let

$$x_i = \frac{1}{(1 - \cos \theta_i)^2}$$

By total probability

$$C\sum_{i} x_i = 1$$

It follows that

$$C = \frac{1}{\sum_{i} x_i}$$

Hence the scattering probability for angle θ_k is

$$f(k) = \frac{x_k}{\sum_i x_i}$$

Predicted values \hat{y}_k are computed as

$$\hat{y}_k = f(k) \sum_i y_i = \frac{x_k \sum_i y_i}{\sum_i x_i}$$

The following table shows the predicted values \hat{y} .

The coefficient of determination R^2 measures how well predicted values fit the data.

$$R^{2} = 1 - \frac{\sum_{i} (y_{i} - \hat{y}_{i})^{2}}{\sum_{i} (y_{i} - \bar{y})^{2}} = 0.999$$

The result indicates that $d\sigma$ explains 99.9% of the variance in the data.
